Cooperating Personnel: L. E. Williams, W. Retzlaff

Objectives: Determine the effects of ozone on leaf photosynthesis and tree growth of five different almond cultivars.

Interpretive Summary: An experiment was set up at the Kearney Agricultural Center (-20 SE of Fresno) to determine the susceptibility of five different almond cultivars (Nonpareil, Mission, Butte, Carmel and Sonora) to ozone, the primary air pollutant in the San Joaquin Valley. One-year old nursery trees of each cultivar were planted in 12 open-topped chambers in April 1989. The chambers were divided into three exposure treatments (four chambers/treatment). A clean-air treatment in which incoming air was charcoal-filtered served as a control treatment. The two pollution treatments were an ambient air treatment and an added ozone treatment (ozone partial pressures 2x ambient). Treatments began on June 1 and continued until November 1.

Although we have not completed the analysis of the data, there appear to be substantial differences in susceptibility to ozone between the five cultivars tested. In the twice ambient treatment, Nonpareil trees grew 40 percent less than the control treatment trees whereas the growth of the Mission cultivars was unaffected by the treatments. The Nonpareil cultivar also showed earlier leaf symptoms, decreases in leaf photosynthesis and premature leaf drop in response to the high ozone treatments. According to these measures, Mission was the least affected by ozone and the other cultivars showed intermediate levels of response.

This study documents that differences in ozone susceptibility do exist between almond cultivars grown in California. If air pollution problems continue to increase in the central valley of California it will be important to take these differences in susceptibility into account when planning for the long term viability of the almond industry.

Current Work: The trees are being excavated, dry weights taken, and the information evaluated so that a detailed final report can be written.

1 Photosynthesis and growth response of almond (Prunus dulcis (Mill) D. A. Webb
2 syn. P. amygdalus Batsch) to increased atmospheric ozone partial pressures.†

1 Abstract

2 Uniform nursery stock of five almond cultivars (Prunus dulcis (Mill) D. A.
3 Webb syn. P. amygdalus Batsch, cv. Butte, Carmel, Mission, Nonpareil, and Sonora)
4 propagated on peach (P. domestica L. Batsch.) rootstock were exposed to three
5 different atmospheric ozone partial pressures. The trees were planted in
6 open-top fumigation chambers on 19 April 1989 at the University of California
7 Kearney Agricultural Center located in the San Joaquin Valley of California.
8 Exposures of the trees to three atmospheric ozone partial pressures (charcoal
9 filtered air, ambient air, or ambient air+ozone) lasted from 1 June to 2 November
10 1989. The mean 12-h (0800-2000 h PDT) ozone partial pressures measured in the
11 open-top chambers during the experimental period were 0.038, 0.060, and 0.112
12 $\mu\text{Pa Pa}^{-1}$ ozone in the charcoal filtered, ambient, and ambient+ozone treatments,
13 respectively. Leaf net CO_2 assimilation, trunk cross-sectional area growth, and
14 root, trunk, foliage, and total dry weight of 'Nonpareil' were reduced by
15 increased atmospheric ozone partial pressures. 'Mission' was unaffected by ozone
16 and 'Butte', 'Carmel', and 'Sonora' were intermediate in their responses.
17 Foliage of 'Nonpareil' also abscised prematurely in the ambient and ambient +
18 ozone treatments. The results indicate that there are almond cultivars that are
19 sensitive to ozone exposure.

20
21 KEYWORDS: OZONE, PHOTOSYNTHESIS, ALMOND, PRUNUS DULCIS, CROSS-SECTIONAL AREA

1 Introduction

2 Ozone (O_3) has been shown to decrease the rate of leaf photosynthesis
3 whether plants are exposed to low partial pressures for an extended time (Reich,
4 1983; Reich and Amundson, 1985; Roper and Williams, 1990; Retzlaff et al., 1991)
5 or to acute partial pressures of the pollutant for a short time (Hill and
6 Littlefield, 1969; Roper and Williams, 1990). Impact of O_3 on the photosynthetic
7 apparatus begins soon after initial exposure at low partial pressures, often with
8 no sign of visible injury (Prinz, 1988).

9 Photosynthetic characteristics of wheat leaves exposed to elevated
10 atmospheric O_3 are similar to those measured in senescing leaves, suggesting O_3
11 induced premature leaf senescence (Lehnher et al. 1987). Prior to abscission
12 of normally senescing leaves, the products of protein degradation usually move
13 out of the leaves for storage in the permanent structures of perennial crops.
14 Nitrogen content of the leaves prior to and just following leaf fall should
15 indicate whether O_3 exposure affects this degradation in association with
16 premature leaf senescence. Nitrogen content of attached Nonpareil almond foliage
17 exposed to $0.030 \mu Pa Pa^{-1} O_3$ was previously found to be higher than the nitrogen
18 content of attached foliage from trees in 0.051 or $0.117 \mu Pa Pa^{-1}$ (Retzlaff,
19 Williams, and DeJong, unpublished data). However, cottonwood leaves that
20 abscised prematurely after five hours of $0.20 \mu Pa Pa^{-1} O_3$ exposure had a higher
21 nitrogen content than leaves that either senesced at the normal time from the O_3
22 exposed trees or leaves that senesced from trees that were not exposed to O_3
23 (Findlay and Jones, 1989). The above information indicates that a distinction
24 should be made with regard to premature leaf abscission in which there is no
25 mobilization of nitrogen and premature leaf senescence involving the normal
26 processes of senescence (Grigal et al., 1976; Oland, 1963; Sacher, 1973).

1 Tree growth reductions appear to be the result of the inhibitory effect of
2 O_3 on photosynthesis (Houston, 1974; Reich and Amundson, 1985; Steiner and Davis,
3 1979; Townsend, 1974; Pye, 1988; Reich, 1983; Retzlaff et al., 1991). Cooley
4 and Manning (1987) hypothesized that growth response of perennial plants to low
5 atmospheric O_3 partial pressures may be the result of changes in assimilate
6 partitioning. Further, these partitioning changes follow different patterns
7 depending upon the plant species and status (vegetative or reproductive). In
8 a recent field study, net photosynthesis and trunk circumference of selected
9 cultivars of almond, plum, apricot, and pear decreased linearly with increasing
10 O_3 partial pressure (Retzlaff et al., 1991). However, in the same study
11 nectarine, peach, and cherry cultivars were unaffected by the O_3 treatments
12 indicating species differences in response to atmospheric O_3 pollution.

13 In 1989 more than 165,000 ha of bearing almond trees were growing in
14 California with 'Nonpareil' comprising 52 % of the total and 'Butte', 'Carmel',
15 'Mission', and 'Sonora' comprising 1, 12, 10, and <1 percent, respectively
16 (Tippet et al., 1989). The San Joaquin Valley fruit production region is
17 characterized by ambient O_3 partial pressures that consistently exceed U. S.
18 Environmental Protection Agency standards of $0.12 \mu Pa Pa^{-1}$ averaged over 1-hour
19 (Cabrera et al., 1988). Previous research has indicated that 'Nonpareil' almond
20 is one of California's most O_3 susceptible tree crops (Retzlaff et al., 1991;
21 McCool and Musselman, 1990). Thus, almond is potentially at risk from O_3 air
22 pollution in the San Joaquin Valley.

23 Therefore, the purpose of this study was to determine the physiological and
24 growth responses of five commercial almond cultivars to three different
25 atmospheric partial pressures of O_3 . If cultivar differences in response to O_3
26 occurred, we were interested in determining their relationship to premature leaf
27 senescence and changes in assimilate partitioning.

1 Materials and Methods

2 Plant Materials and O₃ Treatments

3 Nursery stock of five almond cultivars (Prunus dulcis (Mill) D. A. Webb syn.
4 P. amygdalus Batsch, cv. Butte, Carmel, Mission, Nonpareil, and Sonora) were
5 planted 19 April 1989 in twelve permanent open-top chambers at the University of
6 California Kearney Agricultural Center near Fresno, California (30° 40' N 119°
7 40' W). Trees were on Nemaguard peach (P. domestica L. Batsch) rootstock and
8 trunk diameters at planting were 1.27 cm for 'Butte', 'Carmel', 'Mission', and
9 'Nonpareil' and 0.95 cm for 'Sonora'. All trees were uniformly pruned at
10 planting to a height of 70 cm and one tree of each cultivar was planted per
11 chamber.

12 Cultural practices for these trees were the same as those used commercially
13 to establish young orchards. Trees were flood irrigated approximately once a
14 week throughout the growing season.

15 The open-top chambers used in this study were igloo shaped with a 3.7 x 3.7
16 m square base and a 3.1 m diameter circular open-top 2.7 m above the chamber
17 floor. Chamber frames were constructed of metal conduit with the walls
18 consisting of 12 mil clear polyvinyl plastic. Air ducts within the chambers were
19 two 20 cm and two 15 cm diameter PVC pipes that extended along the chamber floor
20 from one side wall to the other (3.7 m long) equidistant from one another. Holes
21 (5 x 13 cm) were cut in the PVC pipe 31 cm apart to permit air flow upwards into
22 the chambers. Plastic walls were put on the chambers 29-31 May 1989 and blowers
23 were turned on at that time. Blowers provided approximately 67.1 m³ min⁻¹ air,
24 enough flow to change the air volume in the chambers 2 times/minute. Chamber
25 blowers were operated 24 hours per day. Plastic chamber walls were removed on
26 28 November 1989.

1 O₃ treatments imposed in this study were charcoal filtered air (C), ambient
2 air (A), and ambient air+O₃ (T). Treatments were randomly assigned to a chamber
3 and there were four replications of each treatment. O₃ treatments were initiated
4 on 1 June and continued until 2 November 1989. O₃ partial pressures in the
5 chambers were measured with a Dasibi (Glendale, CA) Model 1003 AH O₃ Analyzer.
6 Calibration occurred weekly and involved cleaning and frequency count checks.
7 An Apple IIe (Cupertino, CA) microcomputer interfaced with Cyborg's (Newton, MA)
8 Integrated System for Automated Acquisition and Control (Model 91A) permitted
9 sequential sampling of chamber O₃ partial pressure hourly from 0800 to 2000 hr
10 Pacific Daylight Time (PDT) daily. Chambers were connected to the monitoring
11 system via teflon tubing and solenoid valves. Inlets for air samples were
12 suspended 1 meter above the soil in the center of each chamber (at the
13 approximate mid-point of the plant canopy). Air from each chamber was passed
14 through the monitoring system for 2 minutes prior to measuring O₃ partial
15 pressures to permit residue purging from common sampling lines and the O₃
16 monitor.

17 O₃ for the ambient air+O₃ (T) treatment chambers was generated from dry
18 ambient air with an OREC (Phoenix, AZ) Model 03B-AR/O O₃ Generator and delivered
19 by teflon tubing to the delivery air stream of these chambers. The air was dried
20 by a General Cable Corp. (Westminster, CO) Puregas Heatless Air Drier (Model
21 F200A109-132). The O₃ generator was computer automated to operate at full
22 potential from 0800 to 2000 hr PDT. This resulted in O₃ partial pressures
23 approximately 2 times ambient.

24 Final O₃ partial pressure data analysis was conducted utilizing the means
25 procedure (PROC MEANS) of the statistical analysis system (SAS Institute, 1985).
26 O₃ 12-h means (0800-2000 hr PDT) and the cumulative number of hours greater than
27 0.10 and 0.20 $\mu\text{Pa Pa}^{-1}$ (O₃ partial pressures of 0.10 and 0.20 $\mu\text{Pa Pa}^{-1}$ are

1 equivalent to O_3 concentrations of 0.10 and 0.20 $\mu\text{l l}^{-1}$) were calculated for each
2 treatment. These O_3 partial pressures were used to assess effects of O_3
3 pollution on photosynthesis and growth of five almond cultivars.

4 5 Gas Exchange

6 One month after treatment initiation, leaf net CO_2 assimilation was measured
7 on all cultivars (one cultivar per day over a five day period). This process was
8 repeated at monthly intervals and at the end of the study each cultivar had been
9 measured five times. On each measurement day, leaf net CO_2 assimilation was
10 measured on four leaves from each tree of a particular cultivar in every
11 treatment/chamber (16 leaves/treatment, 48 total leaves measured per sample day).
12 Fully expanded leaves that had been in direct sunlight prior to data collection
13 were selected for measurement. These leaves were from similar canopy positions
14 and were above the last fully expanded leaf on 8 June 1989 near the point where
15 the shoots were tagged for length measurements. Measurements were made between
16 1030 and 1130 h. Leaf temperatures ranged from 22 to 30 °C across all dates and
17 Photon Fluence Rate was greater than 1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$ before 1 November and
18 greater than 600 $\mu\text{mol m}^{-2} \text{s}^{-1}$ on 1 November. Following each measurement, sample
19 leaves were harvested and both leaf dry weight and Kjeldahl nitrogen were
20 determined for each leaf.

21 Photosynthesis measurements were made using an Analytical Development
22 Corporation (Hoddesdon, England) Portable Infrared Gas Analyzer (IRGA) (Model
23 LCA-2), Air Supply Unit with Mass Flowmeter (Model ASUM), Data Processor for the
24 LCA-2 (Model DL-2), and a broad-leaf Parkinson Leaf Chamber. The IRGA was used
25 in the differential mode. Air for the leaf chamber was taken from inside of the
26 open-top chamber in which the tree was growing. Data were recorded on the data
27 processor until all measurements on that particular date had been taken.

1 Growth Measurements

2 From 1 June 1989 (treatment initiation) and at monthly intervals through 1
3 November 1989, circumference of each tree trunk was measured. Painted bands,
4 fifteen centimeters above the soil-line, were used as reference points in order
5 to minimize measurement errors. Increase in trunk cross-sectional area was
6 calculated monthly from the circumference data.

7 Four growing shoots per tree were tagged on 8 June 1989 above the last fully
8 expanded leaf on all cultivars so that any increases in branch length and leaf
9 number above this point could be determined. In all five cultivars, the shoot
10 length and leaf number determinations were made on 30 June, 2 and 31 August, 28
11 September, and 7 November 1989. Trees were inspected for foliar symptoms of O₃
12 injury when measurements were taken. Premature leaf fall was measured by
13 collecting leaves from the ground below each tree on 2, 24, and 31 October 1989.
14 On 4 December 1989, all leaves on the ground below the trees were collected and
15 any remaining foliage on the trees was stripped off in order to determine final
16 foliage biomass.

17 Trees were harvested on 13 February 1990 to determine root, trunk, branch,
18 and total biomass. Roots were removed from the ground by a backhoe and sifted
19 from the soil by hand following the procedure of Araujo and Williams (1988). The
20 soil removed during this procedure was dependent upon the distribution of the
21 trees' roots within the soil volume. Soil volume sifted was approximately 1.75
22 m³ from a 1.2 x 1.2 x 1.2 m hole centered around each individual tree. All tree
23 organs were dried in a forced air oven at 70 °C until there was no further
24 weight change.

25

26

27

1 Carbohydrate Analysis

2 Nonstructural carbohydrates in the roots, trunk, and branches were analyzed
3 by high pressure liquid chromatography (HPLC) as described by Roper and Williams
4 (1989). The trees in this study also contained measurable amounts of sorbitol
5 and therefore it's concentration is included.
6

7 Statistical Analysis

8 A factorial arrangement of three O_3 partial pressures and five cultivars in
9 a split-plot experimental design was replicated four times, with O_3 partial
10 pressure as the main plot. The original analysis was set up in order that
11 repeated measures of photosynthesis and growth through the time-course of the
12 trial could be analyzed by cultivar in a split block design for O_3 partial
13 pressure and date effects. However since there were date effects, no pooling of
14 data across dates was included in the final analysis. So therefore, data
15 collected on each individual date and/or only once during the study were analyzed
16 by a two-way ANOVA. Linear contrasts with the 12-h mean O_3 partial pressures
17 were used for a priori comparisons among treatment means ($\alpha < 0.05$).
18

19 Results

20 O_3 Treatments

21 Cumulative monthly 12-h mean O_3 partial pressures (0800-2000 h PDT) peaked
22 in July and declined to November. By November, 12-h mean O_3 partial pressures
23 of the charcoal-filtered treatment were 63% of the ambient treatment, whereas the
24 high O_3 treatment was 1.9 times that of ambient (Table 1). Monthly 12-h mean O_3
25 partial pressures also peaked in July and declined until November. The number
26 of hours each treatment O_3 partial pressure exceeded 0.10 and $0.20 \mu Pa Pa^{-1}$ also
27 indicated large treatment differences (Table 1).

1 Gas Exchange

2 Increased atmospheric O_3 partial pressure reduced leaf net CO_2 assimilation
3 rate in four of the five almond cultivars during the 1989 growing season (Figure
4 1). Leaf net CO_2 assimilation rate of 'Nonpareil' was reduced within two months
5 after treatments were initiated (August). There were further reductions in
6 'Nonpareil' leaf net CO_2 assimilation on the three remaining measurement dates
7 (September, October, and November) in the ambient and 1.9 times ambient O_3
8 partial pressure treatments. On the last measurement date (November), leaf
9 assimilation rates of 'Butte', 'Carmel', and 'Sonora' also were reduced by
10 increased atmospheric O_3 partial pressures. Increased atmospheric O_3 did not
11 reduce leaf assimilation rate of 'Mission' during this study. It should be noted
12 that leaf assimilation of 'Mission' in the C treatment was less than those of the
13 other two treatments early in the study. Stomatal conductances of the five
14 almond cultivars responded similarly to changing atmospheric O_3 partial pressures
15 as the leaf assimilation response (data not shown).

17 Leaf Nitrogen

18 Seasonal average leaf nitrogen concentration (% dry weight) of 'Butte',
19 'Nonpareil' and 'Mission' was determined from leaf samples removed from the tree
20 on each photosynthetic measurement date. Average leaf nitrogen concentration of
21 'Nonpareil' was reduced by increased atmospheric O_3 partial pressure (Table 2).
22 Leaf nitrogen of 'Butte' was reduced in the T treatment. 'Mission' leaf nitrogen
23 was unchanged by increased atmospheric O_3 partial pressure.

25 Tree Growth

26 Trunk cross-sectional area growth (through 1 November) of 'Butte' and
27 'Nonpareil' was significantly reduced in the T treatment compared to the C

1 treatment (Figure 2, Table 3). Cross-sectional area growth of 'Carmel',
2 'Mission', and 'Sonora' was not affected by increasing O_3 partial pressures.

3 Although shoot growth continued throughout the treatment period, branch
4 length and leaf number of all five cultivars were unaffected by increasing O_3
5 partial pressure (data not shown). Shoot extension growth was highly variable
6 and there were no significant response trends.

7 Above-ground biomass (leaf, branch, and trunk weight) of 'Butte' and
8 'Nonpareil' decreased with increasing atmospheric O_3 partial pressure (Figure 3;
9 Table 3). Above-ground biomass of 'Carmel', 'Mission', and 'Sonora' was not
10 affected by increased atmospheric O_3 partial pressure. Below-ground biomass
11 (root dry weight) of 'Butte', 'Nonpareil', and 'Sonora' decreased with increasing
12 atmospheric O_3 partial pressure (Figure 3; Table 3). Root dry weight of 'Carmel'
13 and 'Mission' was not affected by increased atmospheric O_3 partial pressure.
14 Overall, total tree biomass (total dry weight) of 'Butte' and 'Nonpareil'
15 decreased with increasing atmospheric O_3 partial pressure (Figure 4; Table 3).
16 Total tree biomass of the remaining cultivars was not affected by increased
17 atmospheric O_3 partial pressure. The shoot/root ratio of 'Butte' and 'Nonpareil'
18 decreased in the A treatment compared to the C treatment, but increased in the
19 T treatment (Figure 4; Table 3). Shoot/root ratios of 'Carmel', 'Mission', and
20 'Sonora' increased with increasing atmospheric O_3 partial pressure.

21 22 Carbohydrates

23 The concentration of nonstructural carbohydrates (sugars, starch, and total
24 (sugar + starch)) on a dry weight basis for the permanent organs of all five
25 cultivars was unaffected by increasing atmospheric O_3 partial pressures (data not
26 shown, can be calculated using data in Table 4 and Figure 3). Total
27 nonstructural root carbohydrates of 'Butte' and 'Nonpareil' and the trunk

1 carbohydrates of 'Nonpareil' were reduced in the T treatment when compared to the
2 C treatment on a per tree basis (Table 4). Total nonstructural carbohydrates in
3 the above mentioned organs of the remaining three cultivars were unaffected by
4 increasing atmospheric O_3 partial pressure.

5 6 Foliar Injury

7 Visual injury was observed on the foliage of 'Nonpareil' growing in the T
8 treatment just prior to the first photosynthesis measurements (1 July 1989).
9 Initially, visible injury consisted of chlorotic spots and yellow flecking on the
10 leaf surfaces of older foliage. As time progressed, these chlorotic areas became
11 larger and turned brown due to tissue necrosis. As the trees aged, foliar O_3
12 injury appeared on more and more of the older foliage. Signs of foliar injury
13 were less pronounced on 'Butte', 'Carmel', 'Sonora', and 'Mission'. In these
14 cultivars, injury occurred on the older foliage, but only appeared at the very
15 end of the exposure period.

16 Soon after visible injury became evident in the T treatment, some of the
17 lower/older leaves abscised. Leaves that were collected under the trees on 2 and
18 31 October 1989 indicated that more foliage abscised from 'Carmel', 'Nonpareil',
19 and 'Sonora' in the T treatment than in the C treatment during this time period
20 (Table 5). Increased atmospheric O_3 partial pressures had no effect on leaf
21 abscision of 'Butte' and 'Mission'. Nitrogen concentrations of attached and
22 abscised leaves of the 'Mission' were relatively unaffected by O_3 treatment and
23 abscised leaves had about two-thirds as much nitrogen as the attached leaves
24 (Table 2). On the other hand, leaf nitrogen concentration of the attached
25 'Nonpareil' leaves in the T treatment were significantly lower than in the C
26 treatment and similar to the abscised leaves of all the O_3 treatments. The
27 response of 'Butte' leaves was similar to that of 'Nonpareil' leaves.

1 Discussion

2 Leaf net CO₂ assimilation of 'Nonpareil' was lower in air containing 1.9
3 times ambient O₃ partial pressures compared to charcoal filtered air two months
4 after treatments were initiated (Figure 1). Similar results for this cultivar
5 were reported in a study conducted in 1988 (Retzlaff et al., 1991). In both
6 studies, a decrease in leaf net CO₂ assimilation rate to increased atmospheric
7 O₃ was detected soon after treatments were initiated and remained apparent on
8 each subsequent measurement date. Decreases in leaf net CO₂ assimilation of
9 'Butte', 'Carmel', and 'Sonora' in the present study did not develop as rapidly
10 as those of 'Nonpareil', but by the end of the study period decreases in leaf net
11 CO₂ assimilation of these three cultivars were detected in the 1.9 times ambient
12 O₃ partial pressure treatments compared to the trees grown in air containing less
13 O₃. In contrast, increased O₃ partial pressure did not reduce leaf net CO₂
14 assimilation rate of 'Mission'. Leaf assimilation of 'Mission' in the charcoal
15 filtered treatment was initially lower than that measured in the other two
16 treatments. Later in the season, the Mission leaf assimilation rates in the
17 charcoal filtered air were approximately the same as those in the other two
18 treatments and similar to the other cultivars in the charcoal filtered treatment.
19 The reason for the initial low leaf CO₂ assimilation rates of 'Mission' trees in
20 the charcoal filtered chambers are unknown. Differences in leaf CO₂ assimilation
21 response to increased O₃ partial pressures have been reported previously within
22 the Prunus genus (Retzlaff et al., 1991). However, those differences were among
23 individual species within the Prunus genus, not among different cultivars within
24 a single species as reported here.

25 Plants with high rates of leaf CO₂ assimilation have high uptake rates of
26 O₃ and as a consequence respond more negatively to increased O₃ partial pressures
27 (Reich and Amundson, 1985). Leaf net CO₂ assimilation rates of 'Butte',

1 'Carmel', 'Mission', 'Nonpareil', and 'Sonora' grown in charcoal filtered air,
2 averaged across all measurement dates, were 28.3 ± 1.4 (\pm SE), 24.6 ± 1.5 , 22.0 ± 1.5 ,
3 25.8 ± 1.5 , and 24.4 ± 1.2 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$, respectively. Thus, the photosynthetic
4 potential was similar among all the cultivars and the potential uptake of O_3 by
5 all cultivars should be similar. Therefore, the insensitivity to O_3 by 'Mission'
6 and intermediate responses by 'Butte', 'Carmel' and 'Sonora', when compared to
7 'Nonpareil', apparently were not due to exclusion of O_3 by stomatal regulation
8 (the response of stomatal conductance to O_3 was similar to that of the leaf CO_2
9 assimilation response to O_3 , data not shown) as has been shown for Phaseolus
10 vulgaris L. (Butler and Tibbitts, 1979).

11 Biochemical mechanisms that may impart resistance to a particular air
12 pollutant would include the ability to detoxify the reactive species, an
13 increased threshold for the pollutant, and the ability to repair pollutant damage
14 quickly (Tingey and Taylor, 1982). 'Mission', and to a lesser extent 'Butte',
15 'Carmel', and 'Sonora', apparently have one or more of the above described
16 mechanisms enabling them to reduce the adverse effects of O_3 on metabolism within
17 the leaf.

18 Increased atmospheric O_3 partial pressure resulted in reduced cross-
19 sectional area growth and biomass accumulation (Figures 2 and 3) of the almond
20 cultivars in which photosynthesis was reduced and premature leaf abscission
21 occurred (Table 5). Cross-sectional area relative growth rate of 'Nonpareil'
22 almond previously was shown to decrease linearly with increased atmospheric O_3
23 partial pressure (Retzlaff et al., 1991). Further, trunk caliper of 'Nonpareil'
24 almond was reduced following a two year exposure regime of $0.25 \mu\text{Pa Pa}^{-1} \text{ O}_3$
25 (McCool and Musselman, 1990). The lack of a cross-sectional area growth response
26 in 'Mission', 'Carmel', and 'Sonora' apparently is related to the lack of a
27 reduction in photosynthesis to increased atmospheric O_3 partial pressures until

1 late in the season. Similarly, in red spruce (*Picea rubens*), neither
2 photosynthesis nor growth were affected by a range of atmospheric O_3 partial
3 pressures (Taylor et al., 1986; Laurence et al., 1989).

4 A conceptual model has been proposed to describe the effects of O_3 on the
5 partitioning of assimilates in plants (Cooley and Manning, 1987). It states that
6 under conditions of low partial pressures of O_3 ($0.05 - 0.10 \mu Pa Pa^{-1}$) perennial
7 plants divert assimilate to leaves at the expense of the roots, while at higher
8 partial pressures ($> 0.10 \mu Pa Pa^{-1}$) partitioning of carbon to all sinks is
9 decreased (due to a reduction in the production of photosynthates) with a
10 concomitant reduction in growth. Results obtained in this study allowed us to
11 examine differences in the partitioning of assimilates of almond cultivars that
12 were either sensitive or tolerant to O_3 , and to relate this data to the model of
13 Cooley and Manning.

14 The accumulation of total tree biomass by 'Carmel', 'Mission', and 'Sonora'
15 was not significantly affected by increasing O_3 partial pressures (Figure 3).
16 However, as the mean seasonal O_3 partial pressure increased the shoot/root ratio
17 of these three cultivars increased, albeit small for 'Mission' (Figure 4). There
18 was a linear reduction in biomass accumulation as a function of the mean seasonal
19 O_3 partial pressure for 'Butte' and 'Nonpareil'. The shoot/root ratio for both
20 of these cultivars decreased in going from 0.038 to $0.060 \mu Pa Pa^{-1}$ O_3 and then
21 increased at the highest seasonal mean O_3 partial pressure ($0.112 \mu Pa Pa^{-1}$).
22 The three less sensitive cultivars ('Carmel', 'Sonora', and 'Mission') responded
23 as predicted by Cooley and Manning (1987). Less carbon was allocated to the
24 roots and more to the above ground organs such that total tree biomass was
25 unchanged in the three O_3 treatments (Figures 3 and 4). This was despite the
26 fact that the actual amount of biomass allocated to the leaves was constant
27 across the seasonal mean O_3 partial pressures for all three cultivars (Figure 3).

1 The amount of carbon allocated to the leaves and branches of the more O₃
2 sensitive ('Butte' and 'Nonpareil') cultivars decreased as the seasonal mean O₃
3 partial pressures increased. This does not agree with the model of Cooley and
4 Manning (1987). The sensitive cultivars responded to O₃ partial pressures less
5 than 0.10 $\mu\text{Pa Pa}^{-1}$ as would have been predicted by the model to O₃ partial
6 pressures greater than 0.10 $\mu\text{Pa Pa}^{-1}$. The exception was the fact that the
7 shoot/root ratio decreased at the ambient O₃ partial pressure. The results
8 presented here and elsewhere (Mortenson and Skyre, 1990) indicate that
9 partitioning of dry matter will differ depending upon both the sensitivity of the
10 plant to O₃ and the partial pressure to which the plants are exposed.

11 There was no effect of O₃ partial pressure on the concentration of
12 nonstructural carbohydrates in the permanent structures of the trees. However,
13 as biomass of an organ decreased due to increased partial pressures of O₃, the
14 total amount (g tree⁻¹) of nonstructural carbohydrates found in that organ
15 decreased (Table 4). This differs from the assumptions of Cooley and Manning
16 (1987) and results of a study on Pinus ponderosa Laws. seedlings (Tingey et al.,
17 1976). It is believed that air pollution may cause photosynthates to be retained
18 in the leaves or stems either due to a reduction in their translocation or
19 increased utilization due to a stimulation of respiration needed for repair
20 processes. However for almond, while increasing O₃ partial pressures decreased
21 the allocation of carbon to an organ, due to less available photosynthate, the
22 relative partitioning of carbohydrates for structural and nonstructural purposes
23 did not change. Data similar to this (reduced carbon allocation but no changes
24 in carbon partitioning) have been found when field-grown grapevines (Vitis
25 vinifera L.) are irrigated at rates resulting in different soil water contents,
26 including deficits (L.E. Williams, unpublished data).

1 It is interesting to note that the dry weight of the 'Carmel', 'Mission' and
2 'Sonora' trees actually increased from the charcoal filtered air treatment (0.038
3 $\mu\text{Pa Pa}^{-1}$) to the ambient ($0.060 \mu\text{Pa Pa}^{-1}$) O_3 treatment. All trees in this study
4 were pruned to the same approximate fresh weight at planting (229 g tree^{-1}).
5 Even though 'Butte' and 'Nonpareil' responded negatively to increased O_3 partial
6 pressures, compared to the other three cultivars, final tree dry weight of the
7 two was the greatest in the ambient treatment and 'Butte' was the greatest in the
8 twice ambient treatment (Figure 4). In the charcoal filtered treatment the
9 average dry weight of 'Butte' and 'Nonpareil' (2400 g tree^{-1}) was approximately
10 70% greater than the average weight (1400 g tree^{-1}) of the other three cultivars.
11 The rapid growth of these two cultivars in the charcoal filtered air chambers may
12 have reduced the availability of solar radiation, mineral nutrients, or water to
13 the other three cultivars, reducing their potential growth. Thus, when 'Butte'
14 and 'Nonpareil' experienced stress (ambient O_3 partial pressures) and their
15 growth was reduced, 'Carmel', 'Mission', and 'Sonora' were able to compete more
16 effectively inside the ambient O_3 chambers and their growth was greater than that
17 in the charcoal filtered treatment.

18 The data compiled in Figure 4 is similar to that found with tomato
19 (*Lycopersicon esculentum* Mill.). Temple (1990) found that the most productive
20 tomato cultivar was the most susceptible to O_3 and the least productive the most
21 resistant. In this study the fastest growing almond cultivars were the most
22 sensitive to increased O_3 partial pressures. However, unlike the tomato study
23 there appears to be a direct relationship between reduction in leaf CO_2 exchange
24 (Figure 1) and vegetative tree growth.

25 Foliage discoloration followed by leaf abscission often occurs following
26 extended periods of chronic O_3 exposure (Prinz, 1988). Keller (1988) found that
27 the life span of leaves of O_3 -sensitive aspen clones was shortened by increased

1 atmospheric O_3 partial pressures. The above and additional data of Lehnherr et
2 al. (1987) and Reich and Amundson (1985) indicates that ambient partial pressures
3 of O_3 may cause premature leaf senescence. The processes of leaf senescence
4 involve the recovery of mineral nutrients by the permanent structures of
5 perennial plants (Grigal et al., 1976; Oland, 1963; Sacher, 1973). If O_3 causes
6 premature leaf senescence followed by abscission (as opposed to just premature
7 leaf abscission), then the concentrations of mineral elements such as nitrogen
8 in leaves that have abscised should be similar to leaves that have not been
9 exposed to O_3 but have aged naturally. There were no differences among O_3
10 treatments in the concentration of nitrogen in fallen leaves regardless of
11 cultivar sensitivity to O_3 or when during the experimental period the leaves
12 abscised (Table 2). This supports the contention that ambient O_3 partial
13 pressures do cause premature leaf senescence. It would also indicate that
14 chronic O_3 stress does not interfere with the recovery of mineral nutrients from
15 leaves of perennial plants during senescence.

16 The lowered nitrogen concentrations of attached leaves exposed to increasing
17 O_3 partial pressures of the sensitive cultivars (Table 2, leaves used to measure
18 net CO_2 assimilation rate) during the growing season also indicates the
19 remobilization of nitrogen long before leaf abscission. This differs from the
20 results of Tingey et al. (1976). They found that total nitrogen in the tops
21 (needles and stems) of *P. ponderosa* seedlings exposed to elevated partial
22 pressures of O_3 were similar to the controls. The reduction in nitrogen in the
23 leaves prior to abscission would also lead to a reduction in the capacity of
24 those leaves to fix CO_2 since there is a linear relationship between leaf
25 nitrogen and net CO_2 assimilation rate for several perennial fruit crop species
26 (DeJong, 1982; Williams and Smith, 1985). However, the remobilization of
27 nitrogen out of the sensitive almond cultivar leaves was not the sole reason for

1 a reduction of net CO₂ assimilation rate in this study. When leaf net CO₂
2 assimilation was expressed as a function of leaf nitrogen (either nitrogen
3 concentration or nitrogen per unit leaf area) the rate was always lower than
4 would have been predicted if there had been a linear relationship between leaf
5 net CO₂ assimilation and nitrogen in this study. For example, net CO₂
6 assimilation rate expressed per unit leaf nitrogen of 'Nonpareil' on the
7 September measurement date for the C, A and T treatments were 0.11, 0.11 and 0.05
8 $\mu\text{mol CO}_2 \text{ mmol N}^{-1} \text{ s}^{-1}$, respectively. As outlined by Heath (1980), there are
9 numerous other possible metabolic causes for the additional reduction in leaf CO₂
10 assimilation of the sensitive almond cultivars.

11 The O₃ response differences in the five almond cultivars appears to be
12 related to their different genetic backgrounds. 'Nonpareil' and 'Mission', which
13 responded to O₃ at opposite ends of the spectrum, are either scions or seedlings
14 of distinctly different European cultivars (Hauagge et al., 1987). 'Butte',
15 which had an O₃ response similar to 'Nonpareil', resulted from a cross of
16 'Mission' (female) and 'Nonpareil' (male) (Hauagge et al., 1987). 'Carmel', with
17 no or slight O₃ responses, similar to 'Mission', is a cross of 'Nonpareil'
18 (female) and 'Mission' (male) (Hauagge et al., 1987). Similarly, 'Sonora' is a
19 cross of 'Nonpareil' (female) and 'Eureka' (male), with 'Eureka' having 'Mission'
20 as a parent (Kester et al., 1984). The lack of effects of chronic O₃ exposure
21 on some of the almond cultivars indicates that it may be possible to breed or
22 select for O₃ tolerance in almond.

23 To date, no correlation between decreases in photosynthesis and/or growth
24 and productivity in response to O₃ has been established for deciduous fruit and
25 nut trees. Yield losses of 10% or greater have been documented in citrus and
26 annual agricultural crops at current ambient atmospheric O₃ partial pressures
27 experienced in California (Olszyk et al., 1988; Olszyk et al., 1990). A ten

1 percent loss in 'Nonpareil' almond yield could reduce the total production value
2 of almonds in California by approximately 26 million dollars. Preliminary yield
3 data from a study currently being conducted by the authors with another Prunus
4 species at the Kearney Agricultural Center indicates that losses due to ambient
5 O₃ are much greater than ten percent.

Figure 1. Leaf net CO₂ assimilation (measured at monthly intervals) of five almond cultivars exposed to season-long atmospheric O₃ partial pressures. Vertical bars represent ± one standard error. Asterisks (*) represent dates on which there was a significant linear treatment effect ($\alpha < 0.05$). n = 16.

Figure 2. Trunk cross-sectional area growth from 1 June to 1 November 1989 of five almond cultivars exposed to season-long atmospheric O₃ partial pressures. Vertical bars represent ± one standard error. Probabilities of statistically significant linear O₃ treatment effects are shown in Table 3. n = 4.
