A Life Cycle Assessment of Greenhouse Gas Emissions for Almond Production in California

Lead Investigator: Alissa Kendall, PhD (amkendall@ucdavis.edu); Co-Investigator: Sonja Brodt, PhD (sbbrodt@ucdavis.edu); Graduate Student Researchers: Elias Marvinney, Weiyuan Zhu; Research Assistant: Sarah Millard

Research Objectives

- Quantify net greenhouse gas (GHG) emissions and energy use in California almond production, based on an accounting of all material and energy inputs, biomass accumulation, and carbon sequestration.
- Generate a modeling tool that will help identify "hotspots" (operations and inputs contributing most to total system emissions and energy use).
- Address the following questions:

How much do off-farm inputs contribute to an orchard GHG footprint, compared to on-farm operations?

To reduce the GHG footprint, is it more important to reduce tractor passes or to reduce pruning?

How will changing from flood to micro-sprinkler irrigation affect an orchard's GHG footprint?

Life Cycle Assessment Approach

- Life Cycle Assessment (LCA) evaluates the energy and material inputs and outputs (product) over a system life cycle (in this study, the life cycle of almond production is measured from nursery to farm gate).
- •Raw material extraction, manufacturing, transportation, in field fuel combustion, and ecological processes are accounted for. This allows a robust assessment of the environmental sustainability of a given process.

Methods

- •Input, yield, and operations data were gathered from UC Davis Department of Agriculture and Resource Economics cost/return studies, farmer and operator survey, literature review, and collaboration with other researchers.
- •Emissions and energy use data for industrial processes were collected from Life Cycle Inventory (LCI) databases provided by GaBi 4, Ecoinvent, and USLCI.
- •Greenhouse gas emissions are expressed as 100-year Global Warming Potential (GWP), calculated according to Intergovernmental Panel on Climate Change (IPCC) guidelines.
- Cogeneration potential was calculated from tree mass at orchard clearing and pruning mass, based on a logarithmic growth model and assuming 95% biomass removed directed to cogeneration (G&F Ag Services LTD, personal communication).
- •Fuel combustion emissions are calculated using the California Air Resources Board (CARB) OFFROAD modeling tool.
- •Soil emissions in response to management and nutrient inputs are estimated using IPCC Tier 2 calculations.

GHG Emissions and Energy Use per

Results and Future Research Directions

- Potential greenhouse gas offsets represent a significant proportion of total almond production emissions (excluding processing and distribution).
- The bulk of energy use and emissions are derived from nutrient management particularly from production of nitrogen fertilizers. This is a hotspot for improvements in energy use efficiency, which may make almond growers eligible for carbon payments under potential future California Air Resources Board emissions offset programs.
- Worst-case assumptions were used to model emissions and energy use, so many individual orchards in California may have substantially lower emissions and energy use.
- Future research will incorporate processing and distribution, spatially explicit variations in inputs and management, and IPCC Tier 3 field emissions models into the system LCA model.

groundwater pumping. Future analyses of surface water use in almond production, and associated upstream energy use in large-scale water projects, may affect these results.

Note: Calculations of energy used for irrigation are based on the assumption of 100% on-farm
